## The problem

- Comparative studies → the evolution of an aggregate outcome for the units affected by the intervention vs the evolution of the same aggregate for the units in the control group.
- The control group might not be a good counterfactual, i.e., it might not represent a good approximation of the treated units in the absence of treatment.
  - Less formal comparisons: e.g., EU vs US; a EU country vs EU28; a country vs its neighbors; etc.
  - Panel data: e.g., Before-and-After or Diff-in-Diff.
- Common trend assumption needs to be satisfied (testable).
- Sometime we are interested in:
  - i. Studying only a single treated unit, because:
    - it is the only observable event-unit pair;
    - different timing of the treatment;
    - need of a unit-specific measure of the effect.
  - ii. Studying the dynamics of effects.

## The problem

- Comparative studies → the evolution of an aggregate outcome for the units affected by the intervention vs the evolution of the same aggregate for the units in the control group.
  - The control group might not be a good counterfactual, i.e., it might not represent a good approximation of the treated units in the absence of treatment.
    - Less formal comparisons: e.g., EU vs US; a EU country vs EU28; a country vs its neighbors; etc.

      - different timing of the treatment;
      - need of a unit-specific measure of the effect.
    - ii. Studying the dynamics of effects.
- The synthetic control method for comparative case studies developed by Abadie et al. (2003 AER, 2010 JASA, 2014 AJPS).

## This presentation

i. Brief presentation of the SCM.

(a) How does it work?

(b) Advantages and Disadvantages.

ii. Conditions for applying the SCM.

- Brief review of the papers using the SCM.

iii. Focus: Measuring the impact on GDP and productivity of EU membership.

## Definition

- SCM is a methodology that provides a systematic way to select comparative case studies.
- It compares the evolution of an outcome variable for a treated unit against the evolution of the outcome for a weighted control group (or synthetic unit).
- Researcher specifies: (1) treatment unit (2) pre-treatment and treatment periods, (3) matching covariates/predictors, and (4) donor units (control group).
- The construction of the synthetic unit is made by searching for a weighted combination of the donor units, so to mimic as close as possible the treated unit's pre-treatment characteristics.
- Then, the synthetic outcome in the treatment period is given by the weighted combination of the donor units' outcome, using the weights computed in the pre-treatment period. The post-treatment difference between the actual and synthetic outcome is interpreted as the treatment effect.

## Example: Germany's reunification (Adabie et al. 2015, AJPS)

FIGURE 1 Trends in per Capita GDP: West Germany versus Rest of the OECD Sample

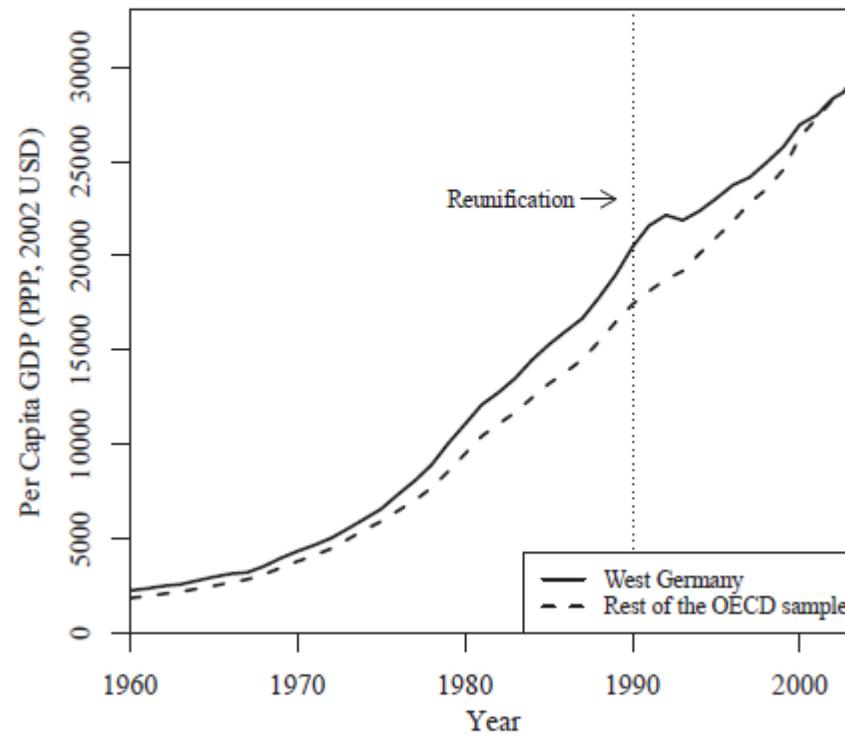

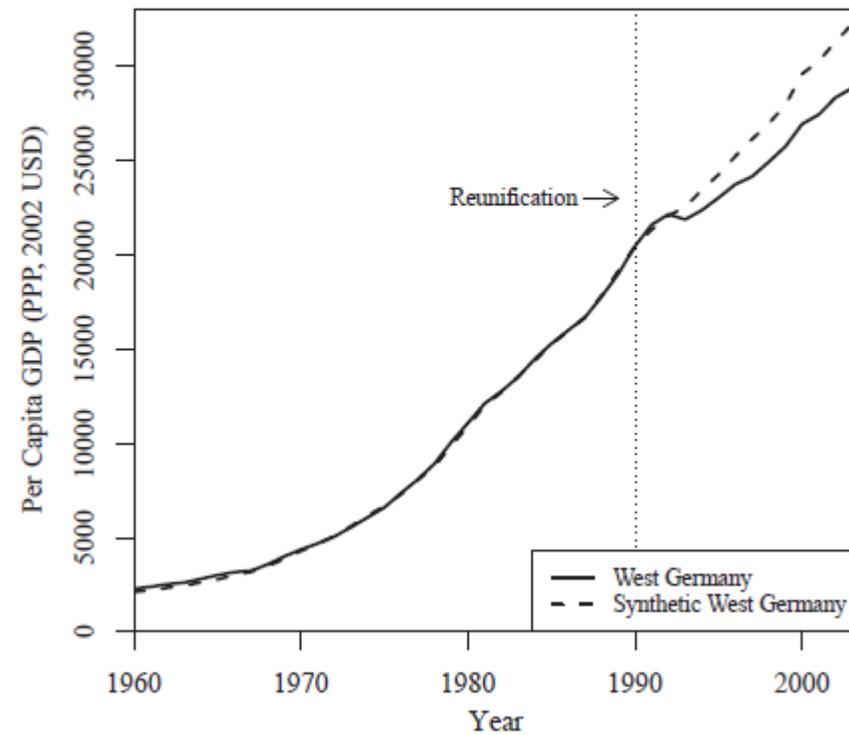

FIGURE 2 Trends in per Capita GDP: West Germany versus Synthetic West Germany

## Control units' weights

Germany's reunification (Adabie et al. 2015, AJPS)

Country	Synthetic Control Weight	Country	Synthetic Control Weight
Netherlands	0.09	Australia	0
New Zealand	0	Austria	0.42
Norway	0	Belgium	0
Portugal	0	Denmark	0
Spain	0	France	0
Switzerland	0.11	Greece	0
United Kingdom	0	Italy	0
United States	0.22	Japan	0.16

## Predictors' balance

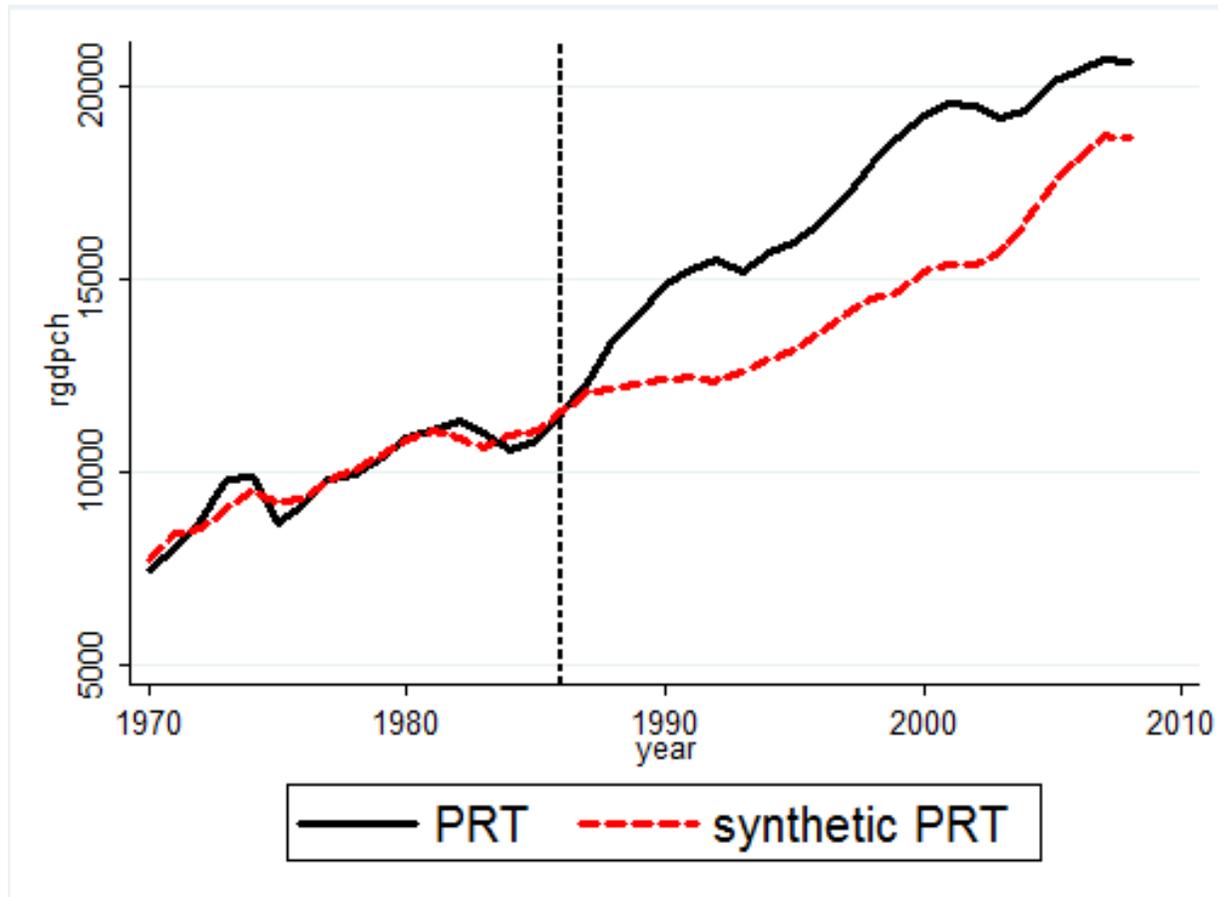

Germany's reunification (Adabie et al. 2015, AJPS)

**TABLE 2 Economic Growth Predictor Means before German Reunification**

	West Germany	Synthetic West Germany	OECD Sample
GDP per capita	15808.9	15802.2	8021.1
Trade openness	56.8	56.9	31.9
Inflation rate	2.6	3.5	7.4
Industry share	34.5	34.4	34.2
Schooling	55.5	55.2	44.1
Investment rate	27.0	27.0	25.9

*Notes:* GDP per capita, inflation rate, trade openness, and industry share are averaged for the 1981–90 period. Investment rate and schooling are averaged for the 1980–85 period. The last column reports a population-weighted average for the 16 OECD countries in the donor pool.

## Example: Campos, Coricelli, Moretti 2014 CEPR dp

Donor	W	Donor	W
ALB	0	JPN	0.066
ARG	0	KOR	0
AUS	0	MAR	0
BRA	0.142	MEX	0.008
CAN	0	MYS	0.001
CHL	0.237	NZL	0.116
CHN	0	PHL	0.239
COL	0	THA	0
EGY	0	TUN	0
IDN	0	TUR	0
ISL	0.19	URY	0

Predictors	PRT	Synth-PRT
Real GDP pc*	9851.037	9839.439
Investment share*	23.669	22.861
Pop. growth*	.005	.0183
Share of agriculture**	21.999	13.751
Share of industry**	30.775	37.725
Tertiary education**	10.578	17.556
Secondary education**	49.59153	66.352

Note: sample of control countries from Bover and Turrini (2010).

\* Source: Penn World Tables.

\*\* source: World Development Indicators.

Note: results are robust to different donor samples and model specifications.

## (A little bit more) technically

- $Y$  is the outcome variable.
- $T=T_0+T_1$ , where  $T_0$  is the pre-treatment and  $T_1$  the treatment period.

$$\tau_{j,t} = Y_{j,t}^I - Y_{j,t}^C, \quad \text{where } Y_{j,t}^C \text{ is unknown for } t > T_0.$$

- $J+1$  units;  $j=1$  is the treated,  $j=2, \dots, J+1$  are potential comparisons (donor pool).
- A synthetic control can be represented by a  $(J \times 1)$  vector of weights  $W = (w_2, \dots, w_{J+1})'$ , with  $0 \leq w_j \leq 1$  for  $j=2, \dots, J+1$  and  $w_2 + \dots + w_{J+1} = 1$ .
  - Let  $X_1$  a  $(k \times 1)$  vector of pre-treatment characteristics of the treated unit.
  - Let  $X_0$  a  $(k \times J)$  matrix of the same pre-treatment characteristics of the donor units.
  - $W^*$  are chosen such that  $X_1 - X_0 W$  is minimized.
    - \* Given  $v$  the relative predictive power of the  $m$ -th variable/characteristic,
    - \*  $W$  minimizes  $\sum_{m=1}^k v_m (X_{1m} - X_{0m} W)^2$
- Abadie et al. (AER 2003, JASA 2010) show that  $\tau_{1,t} = Y_{1,t}^I - \sum_{j=2}^{J+1} w_j Y_{j,t}$ , for  $t > T_0$ .

## Advantages and Disadvantages

The advantages of the SCM:

- i. It allows to estimate the effects of single, unit-specific events.
  - It allows to estimate the heterogeneous effects of the treatment on each of the treated units.
- ii. It allows an assessment of the effects of treatment over time.
- iii. It is transparent about the weights assigned to donor units.
- iv. When estimations are repeated across units, it allows to construct a unit-time specific measure of the treatment effect, which can be used as dependent variables in a regression to explain the heterogeneity of the effects.

Potential problems related to the SCM:

- Post-treatment shocks on the donor units can bias the results.
  - Confidence on the goodness of the synthetic decreases over time.
- It does not allow assessing the significance of the results using standard (large-sample) inferential techniques.
  - Several attempts to solve these problems: placebo-studies, different donor samples.

## Conditions for applying the SCM

i. Choice of the relevant outcome variable.

- So far, SCM has been mostly used in macro studies (time-series needed) → the outcome variable should be likely affected by the treatment.

## Outcome variable: GDP...

The SCM has been applied to study the effects of several events on GDP, e.g.:

- Terrorism in the Basque Country (Abadie and Gardeazabal 2003 AER)
- Natural disasters (Cavallo et al. 2013 REStat)
  - Even extremely large disasters do not display any significant effect on economic growth.
- Germany's reunification (Abadie et al. 2015 AJPS).
  - West Germany GDP fall after reunification.
- Trade liberalizations (Billmeier&Nannicini 2012 REStat).
  - Liberalizations had positive effects in most regions, but more recent liberalizations, in the 1990s and mainly in Africa, had no significant impact.
- The presence of Mafia activities (Pinotti, EJ 2015).
  - Mafia lowered the GDP per capita by 16% in Apulia and Basilicata.
- Civil wars (Dorsett, EJPE 2013; Costalli, Moretti, Pischedda, 2014 wp).
- EU membership (Campos, Coricelli, Moretti, 2014 and 2015 CEPR dp).
- Etc...

## ...but also other aggregate outcomes

Others have looked at different outcomes; eg:

- Effects of political connections on firms' performance (Acemoglu et al. 2016 JFinEc).
- Effects of anti-tobacco regulation on number of smokers (Abadie et al. 2012 JASA).
- Effects of oil discoveries on democracy (Masi and Ricciuti 2016 UNU-Wider wp).
- Etc...

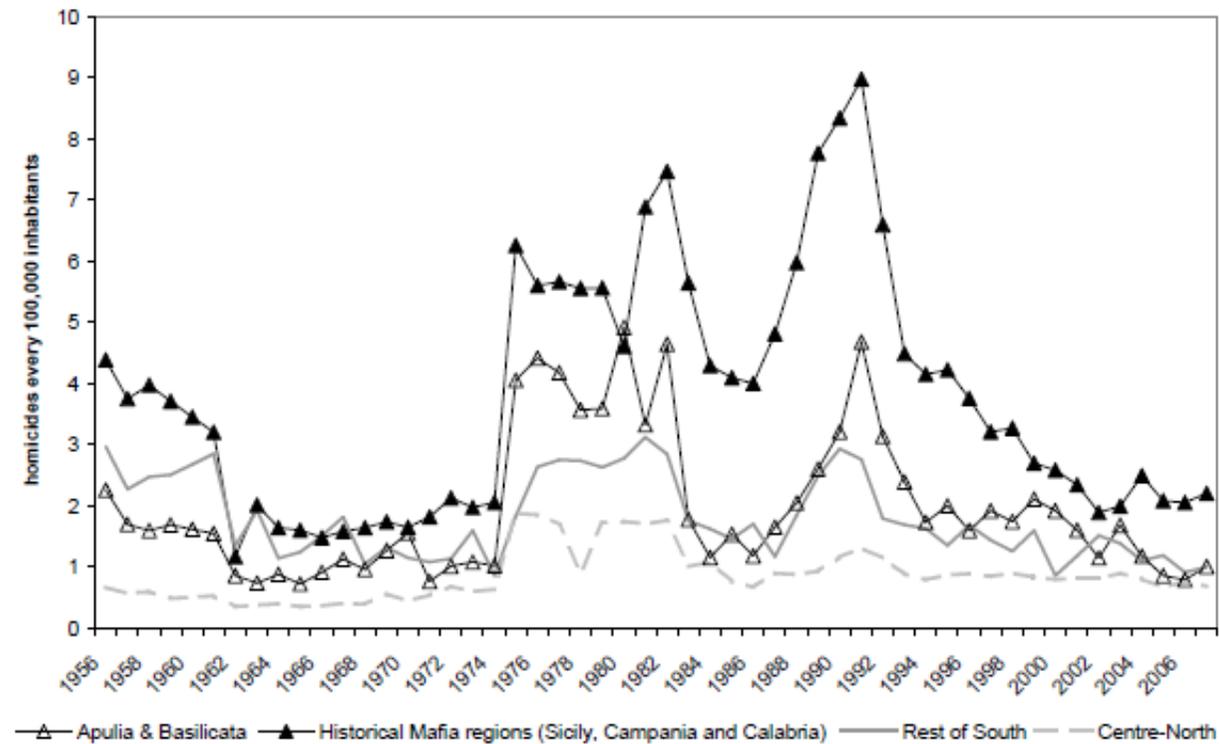

## Conditions for applying the SCM

- i. Choice of the relevant outcome variable.
  - So far, SCM has been mostly used in macro studies (time-series needed) → the outcome variable should be likely affected by the treatment.
- ii. Clear definition of beginning of the treatment.
  - Random shocks (easy); Reforms (anticipation effects?); etc.

## Definition of the treatment unit and treatment period

- E.g.: Pinotti (2015, EJ) on effects of Mafia activities on regional GDP.

Figure 4: murder rate over time across different areas in Italy, years 1955-2007

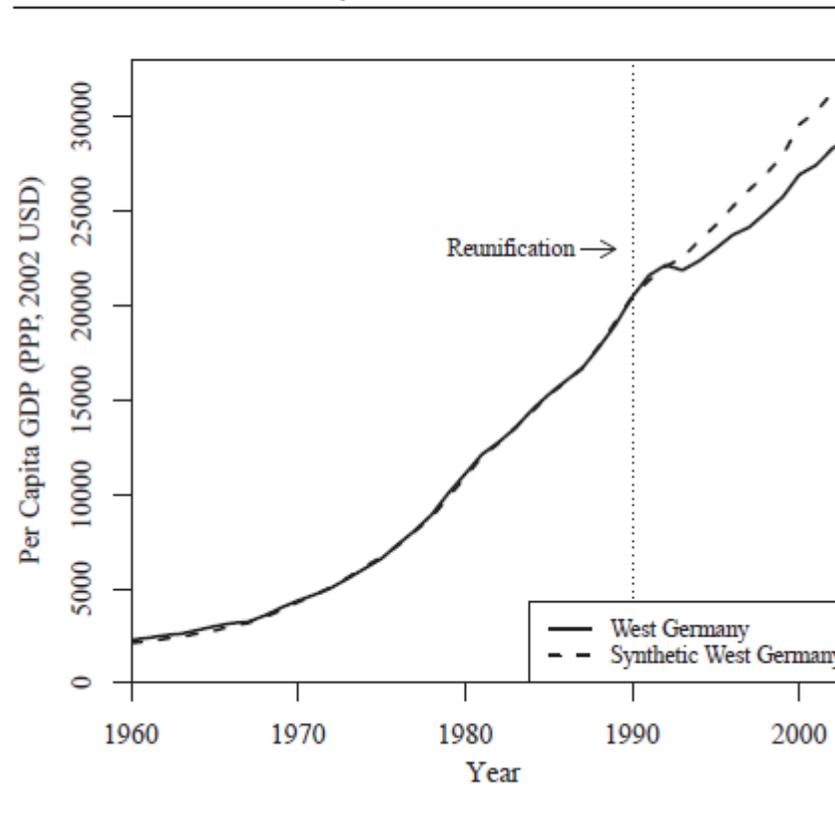

## Conditions for applying the SCM

- i. Choice of the relevant outcome variable.
  - So far, SCM has been mostly used in macro studies (time-series needed) → the outcome variable should be likely affected by the treatment.
- ii. Clear definition of beginning of the treatment.
  - Random shocks (easy); Reforms (anticipation effects?); etc.
- iii. Definition of the pre-treatment period.
  - It should be long enough when compared to the treatment period.
  - Short pre-treatment periods can raise concerns about the goodness of the counterfactual during the treatment period. We need to show that pre-treatment fluctuations of the treated unit's outcome are matched by fluctuations of the synthetic's outcome (data availability constraints? shocks?).

## Definition of the pre-treatment period

(Adabie et al. 2015, AJPS)

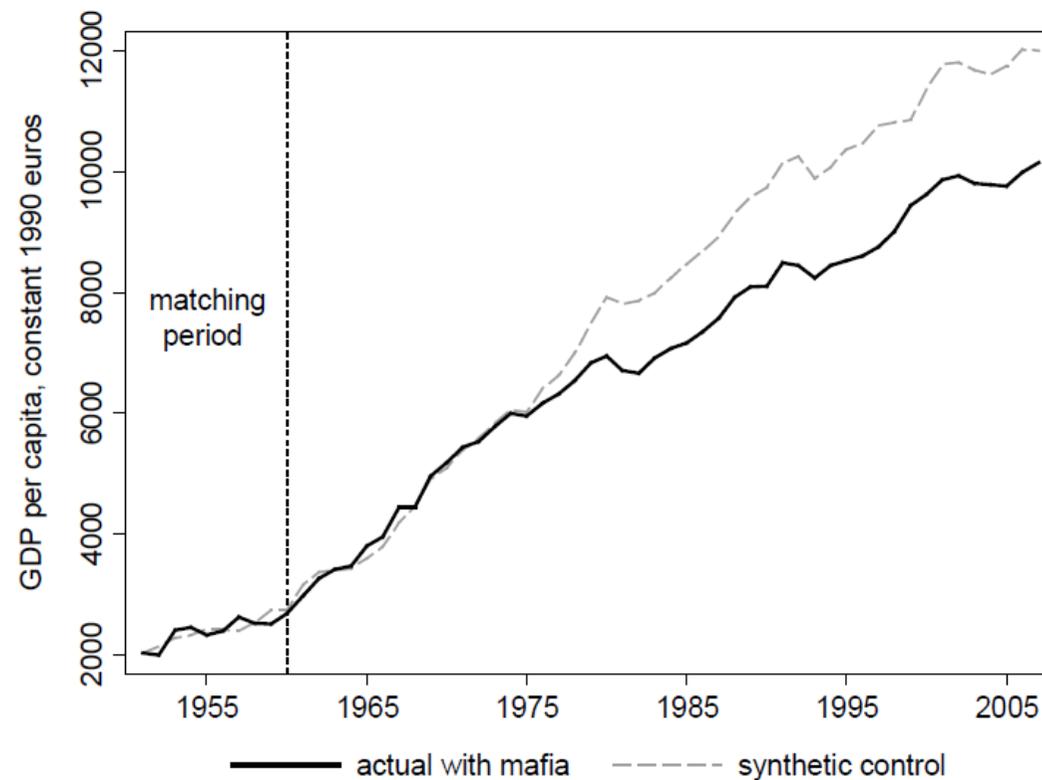

FIGURE 2 Trends in per Capita GDP: West Germany versus Synthetic West Germany

## Pre-treatment matching period and Pre-treatment training period

- Pinotti (2015, EJ) divides the pre-treatment in
  - i. matching period: choice of the weights.
  - ii. training period: projection during the pre-treatment period → no difference expected.

Figure 6: GDP per capita in the treated region and in the synthetic control, years 1951-2007

## Treatment projection period

- Confidence on the goodness of the counterfactual gradually reduces from the treatment year.
- Data availability constraints.
- Shocks.

## Conditions for applying the SCM

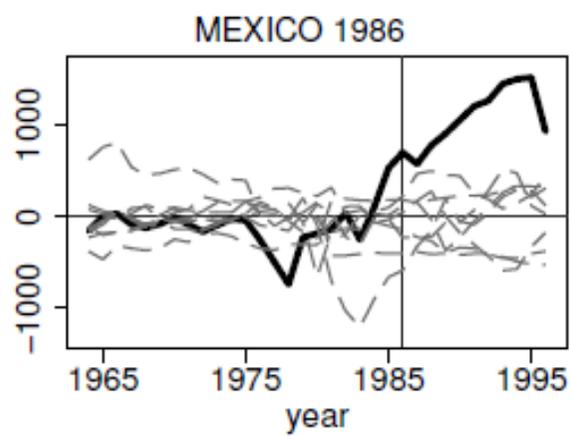

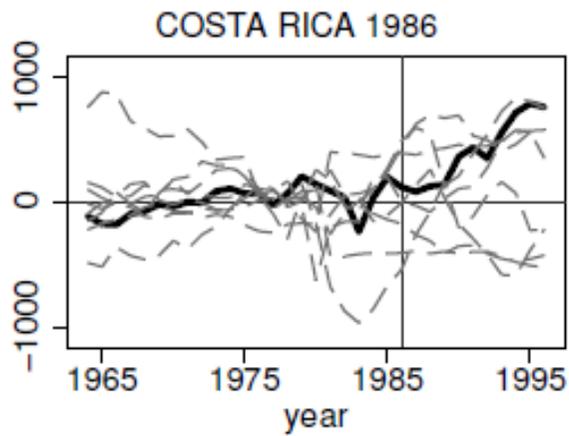

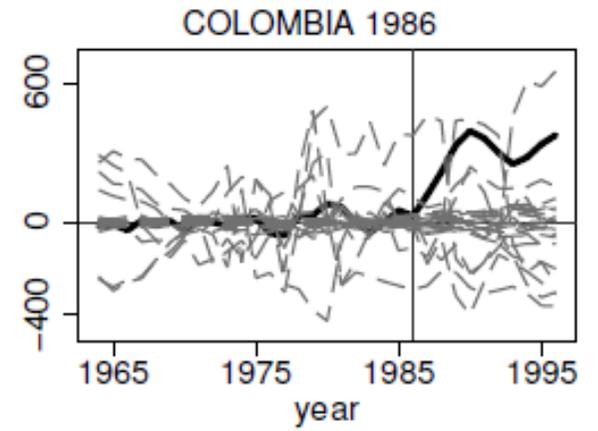

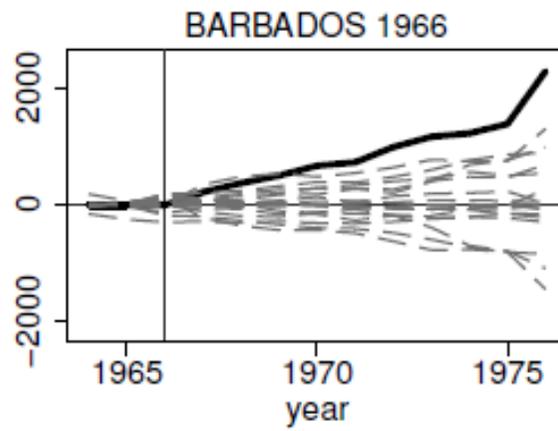

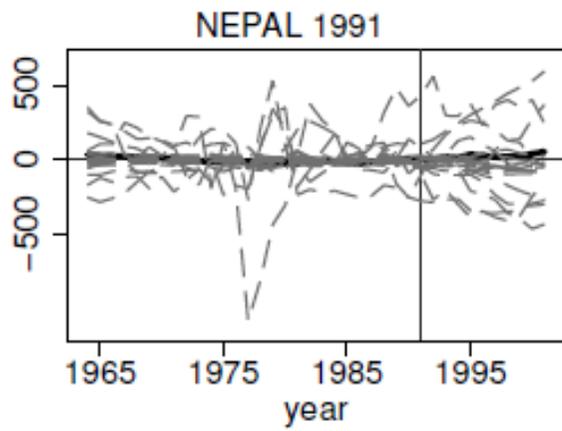

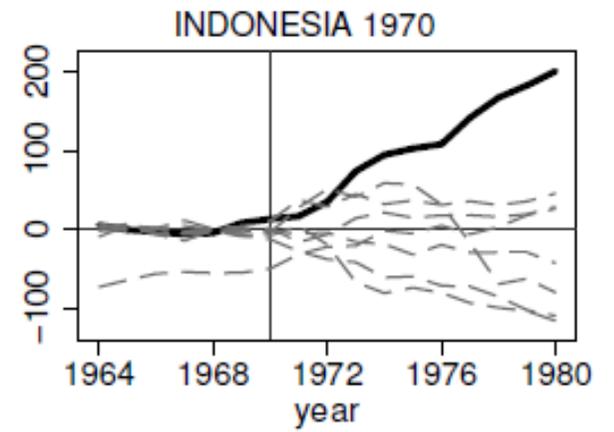

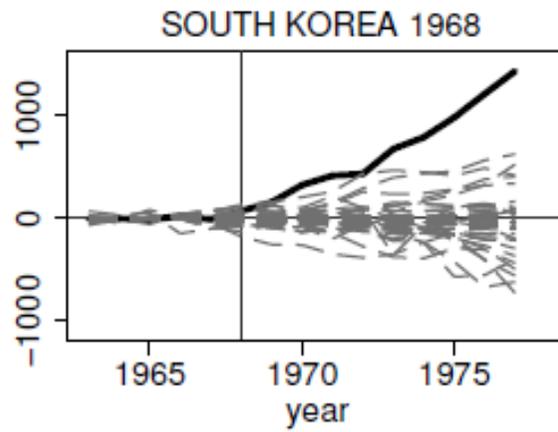

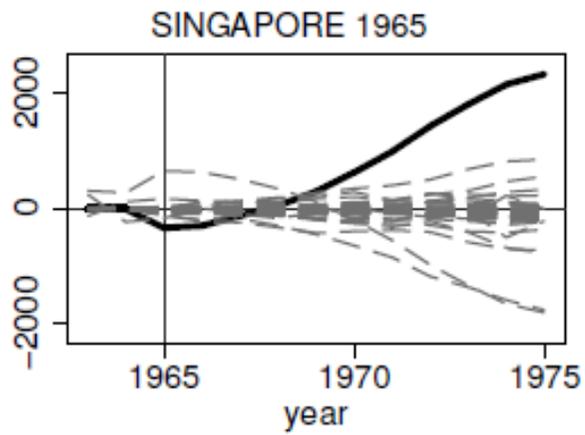

- i. Choice of the relevant outcome variable.
  - So far, SCM has been mostly used in macro studies (time-series needed) → the outcome variable should be likely affected by the treatment.
- ii. Clear definition of beginning of the treatment.
  - Random shocks (easy); Reforms (anticipation effects?); etc.
- iii. Definition of the pre-treatment period
  - It should be long enough when compared to the treatment period.
  - Short pre-treatment periods can raise concerns about the goodness of the counterfactual during the treatment period. We need to show that pre-treatment fluctuations of the treated unit's outcome are matched by fluctuations of the synthetic's outcome (data availability constraints? shocks?).
- iv. Definition of the preferred/main control sample
  - On the base on literature, theory, and goodness of pre-treatment fit.
  - Donor units should not be affected by the treatment (spillovers?) and large idiosyncratic shocks during the entire period of analysis (confounding?).

## Problems with standard inferential techniques

- Post-treatment shocks on the donor units can bias the results.
- This method “does not allow assessing the significance of the results using standard (large-sample) inferential techniques, because the number of observations in the control pool and the number of periods covered by the sample are usually quite small in comparative case studies” (Billmeier and Nannicini, REStat 2013).

## Placebo experiments

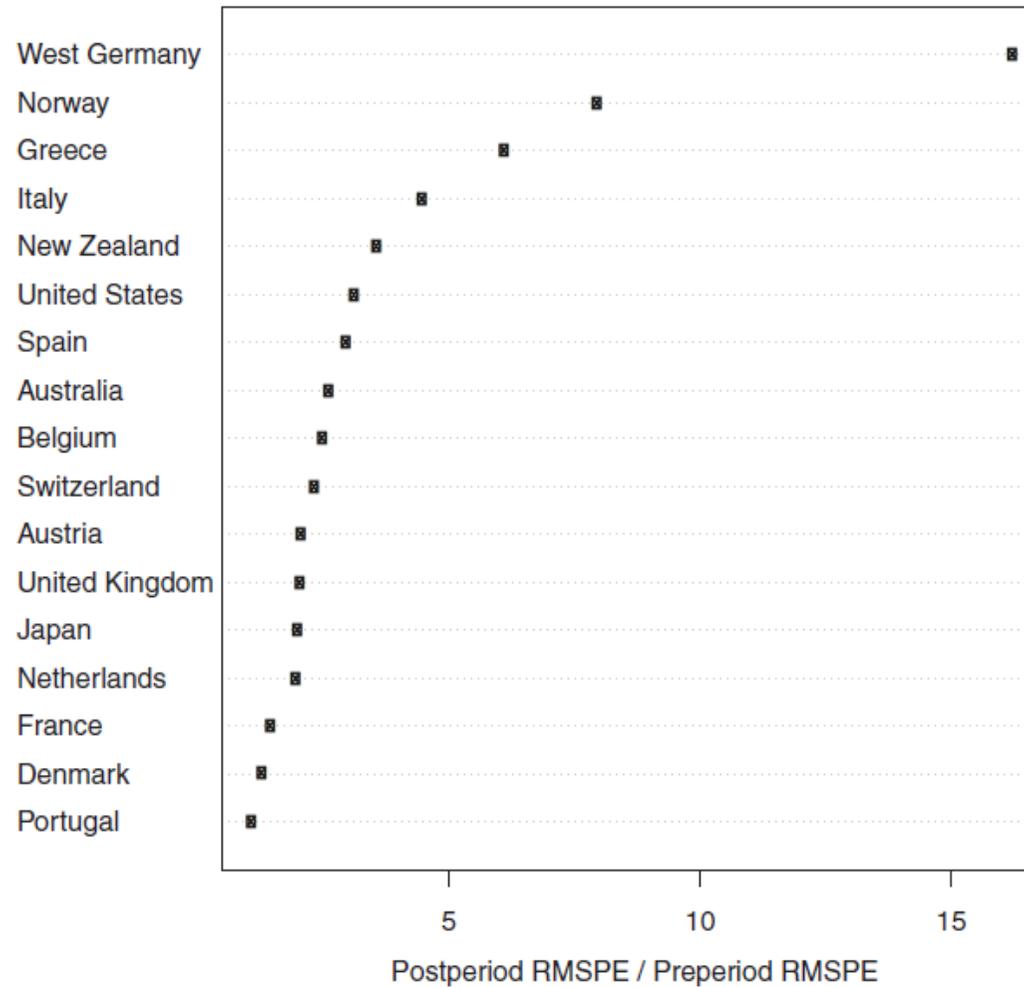

- Construct a synthetic counterfactual for each donor unit using the rest of the donor units as potential controls.
- If the effect on the treated unit is extreme respect to the effects on the donor units (ie. placebo effects), then we can be confident of the significance of the treatment (eg. Abadie et al., 2010, 2014; Billmeier and Nannicini 2012).

## Comparing treated and placebo effects

(Adabie et al. 2015, AJPS)

FIGURE 5 Ratio of Postreunification RMSPE to Prereunification RMSPE: West Germany and Control Countries

## Limits of placebo experiments on donor units

Placebos are informative but

- They do not tell us whether our results are driven by spurious effects.
- They still suffer of small numbers problems.
- For instance (extreme cases):
  - Idiosyncratic shocks can affect some countries in the donor sample but these countries actually take a weight of 0 for the construction of the synthetic country → the effect on the treated is not extreme respect to the effect on the untreated (placebo) countries. However, the estimated effect is not spurious.
  - The effect on the treated is larger than 95% of the placebo effects and the donor countries with larger shocks take a positive weight → the effect on the treated is extreme. However, the estimated effect is spurious.

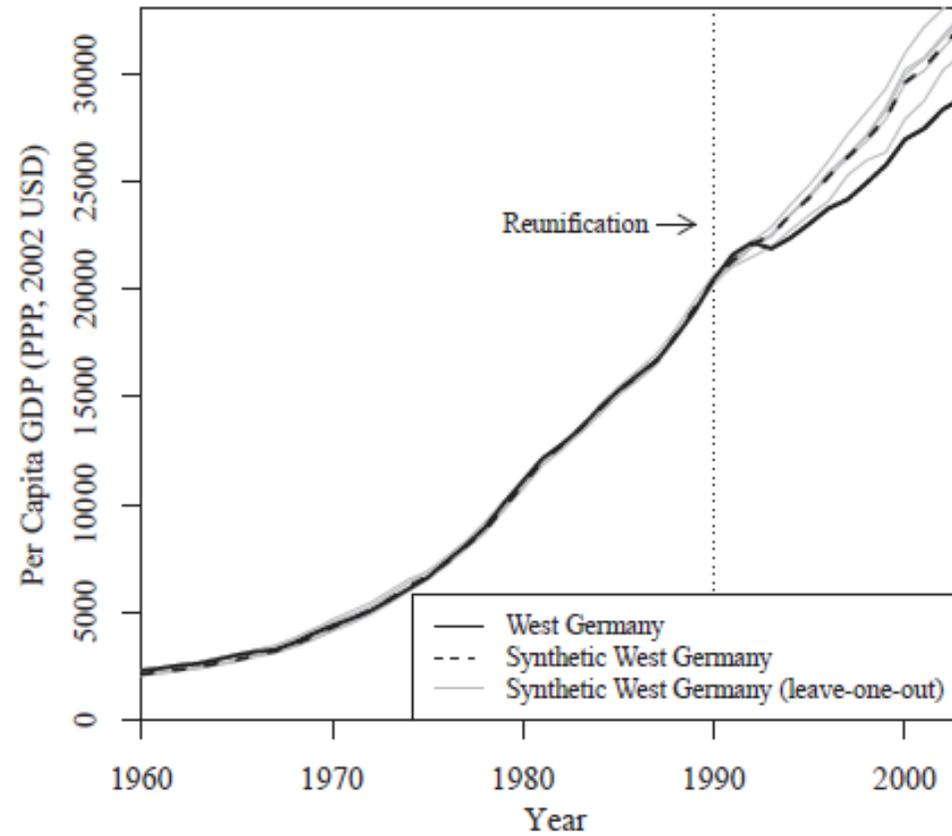

## How to complement placebo evidence?

Try different donor samples...

- Each donor sample has its own probability of being affected by (minor or large) shocks on the donor countries.
- Thus, each set of weight has its own probability to lead to biased results.
- Eg: Billmeier and Nannicini (2012) run to alternative experiments (whole sample and neighboring countries).
- Eg: Abadie et al (2010, 2014) exclude one country per time from the donor sample and re-run the estimation on the treated unit.

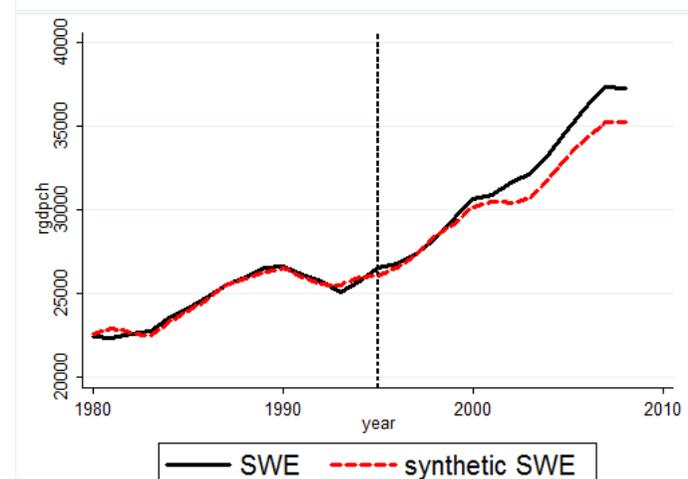

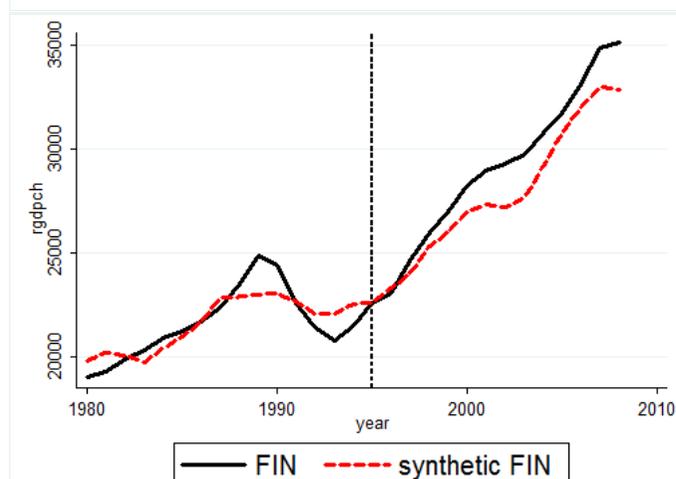

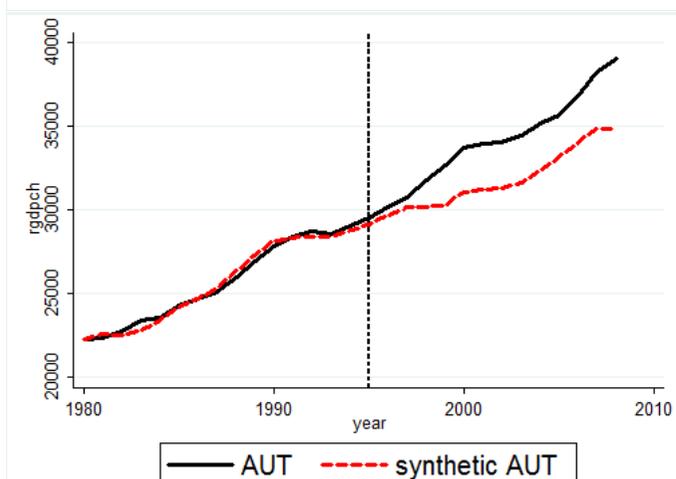

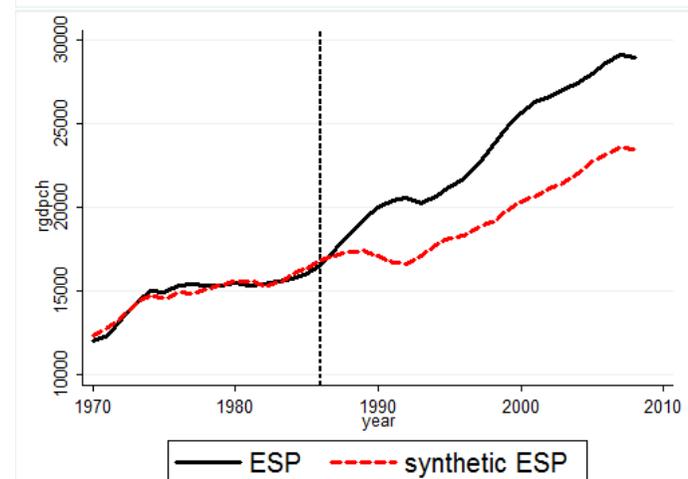

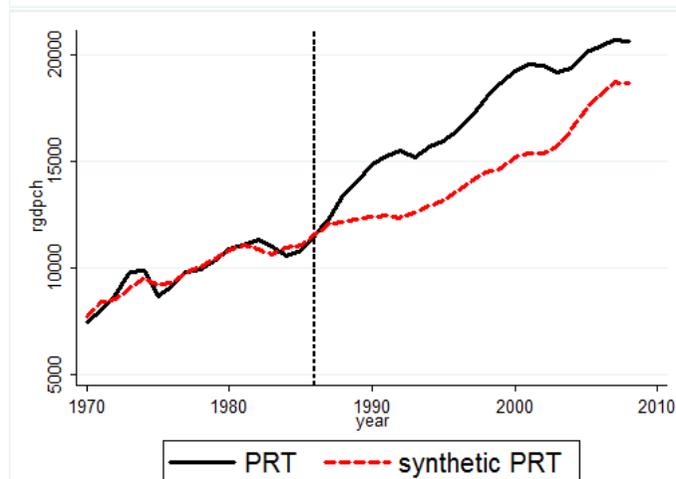

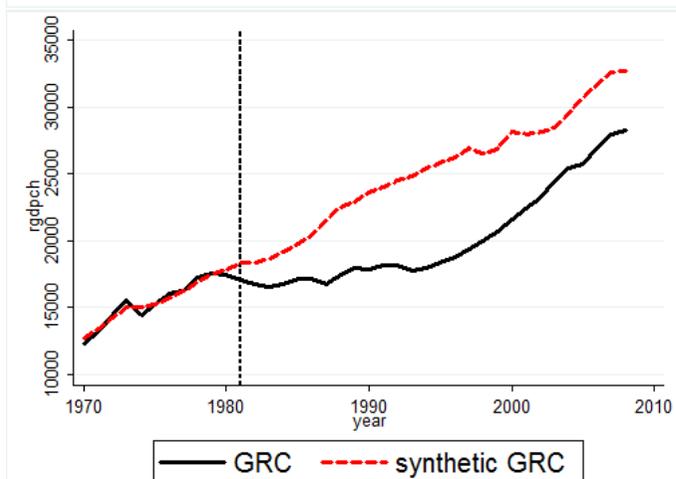

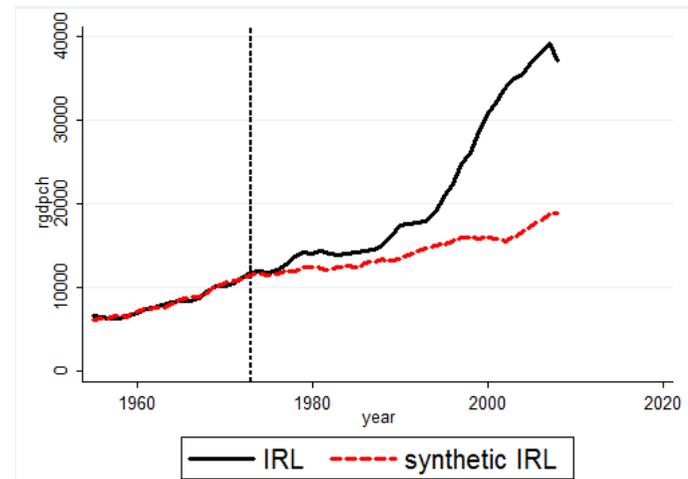

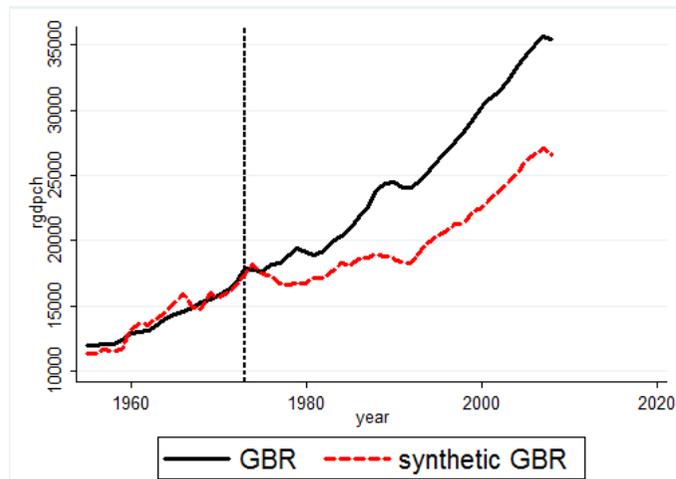

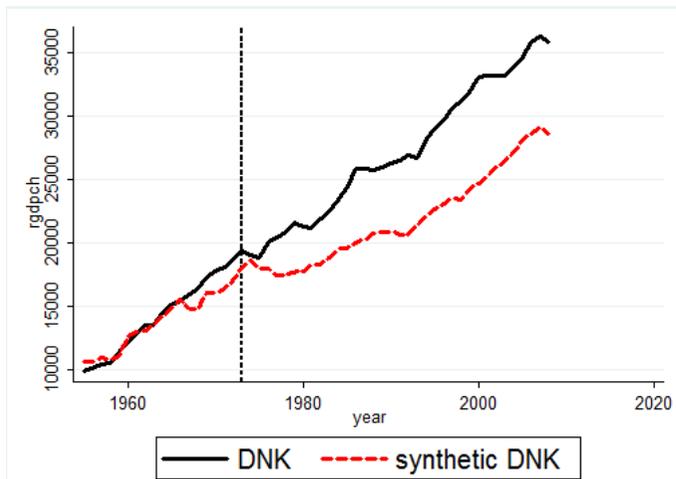

## Leave-one-out

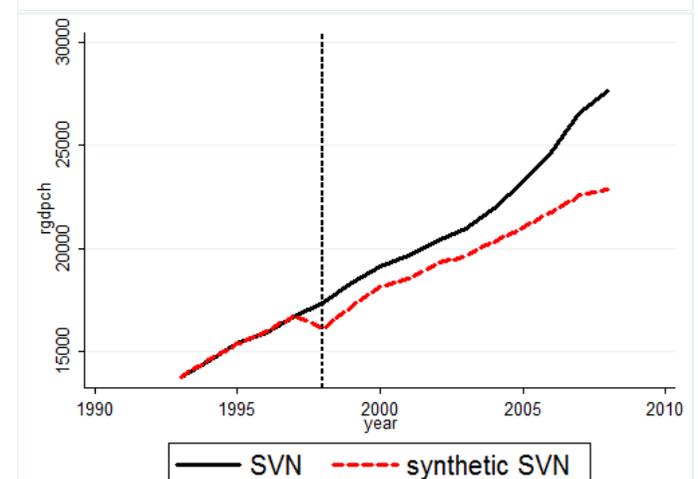

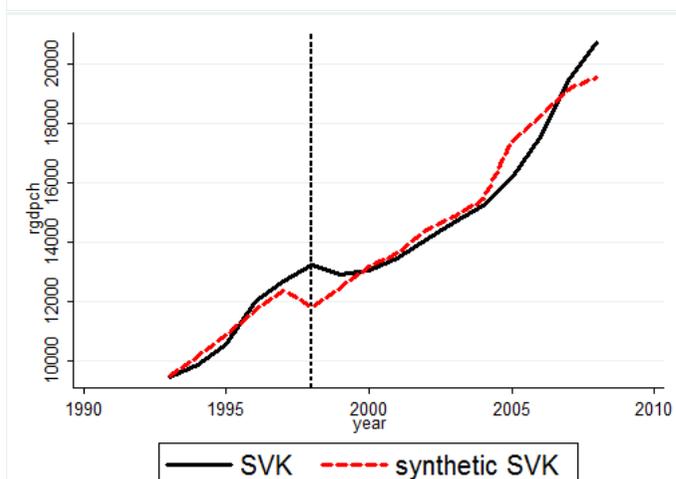

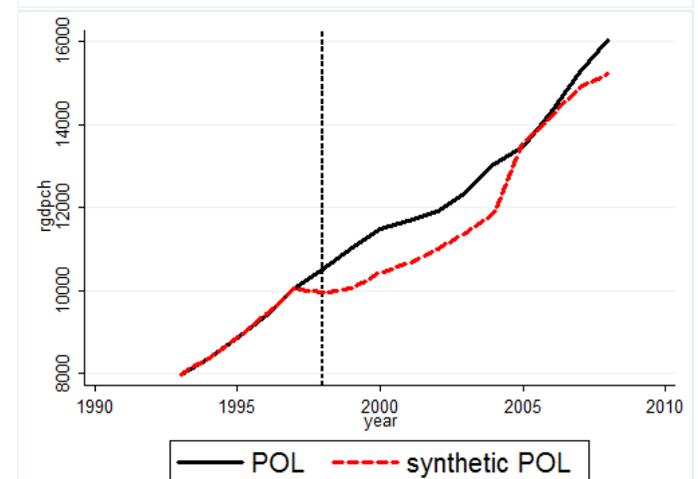

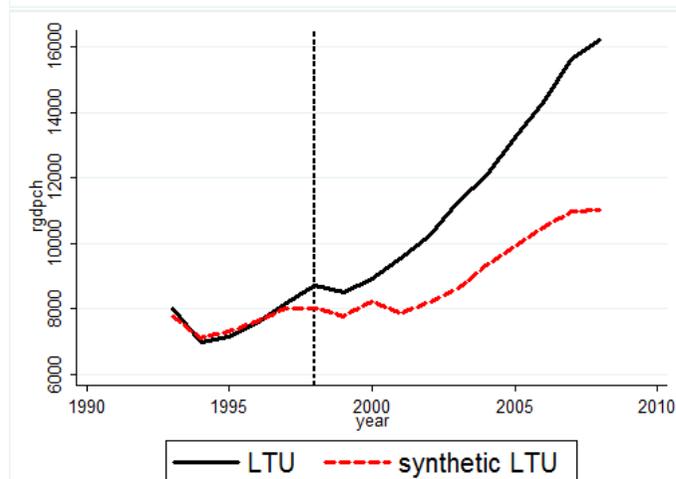

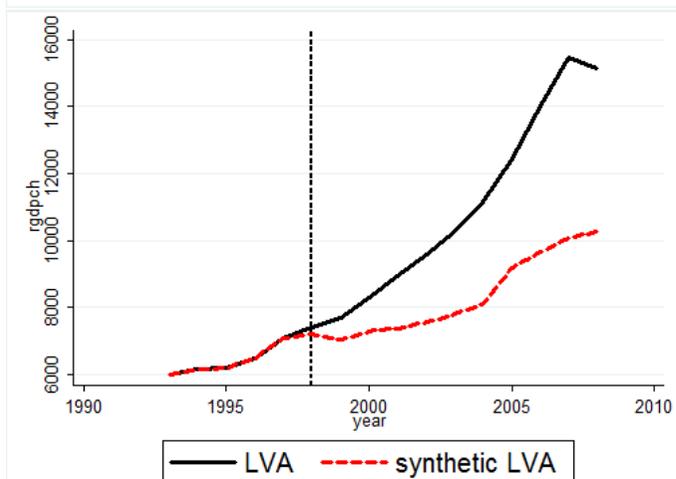

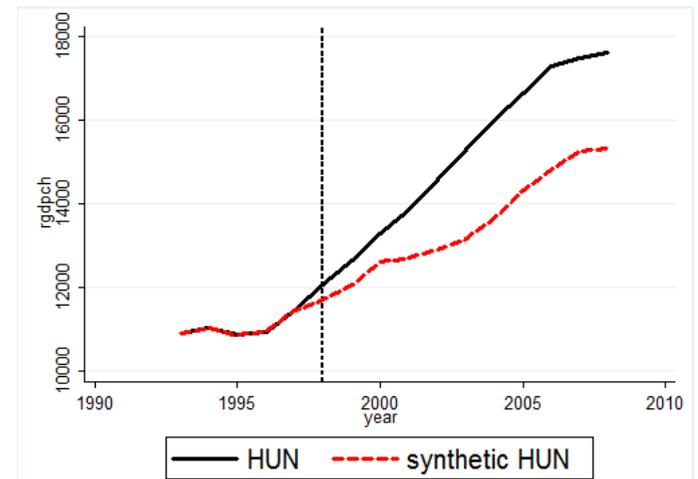

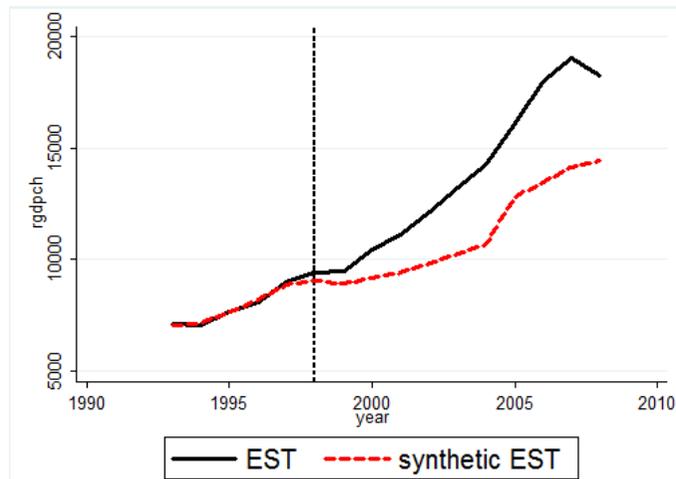

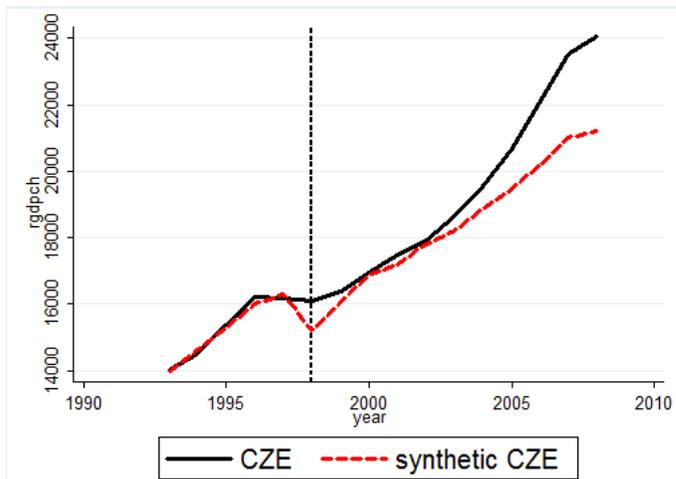

FIGURE 6 Leave-One-Out Distribution of the Synthetic Control for West Germany

## EU Membership (Campos et al. 2014, CEPR dp)

- *Problem*: False perception of abundance of evidence on economic benefits of EU membership. As noted by Eichengreen the main difficulty is to construct relevant counterfactuals; his guess is that EU membership has between +5 and +20% effect on GDP.
- *Question*: What would have been the growth rates of per capita GDP and labor productivity in EU countries had they not become full-fledged EU members?
- *Method*: SCM.
- *Sample*: Non-founding EU countries (17 countries for the 1973, 1980s, 1995, and Eastern EU enlargements).
- *Results*: In case of non-EU, in these countries GDP per capita would have been, on average, 10% lower (but large heterogeneity).

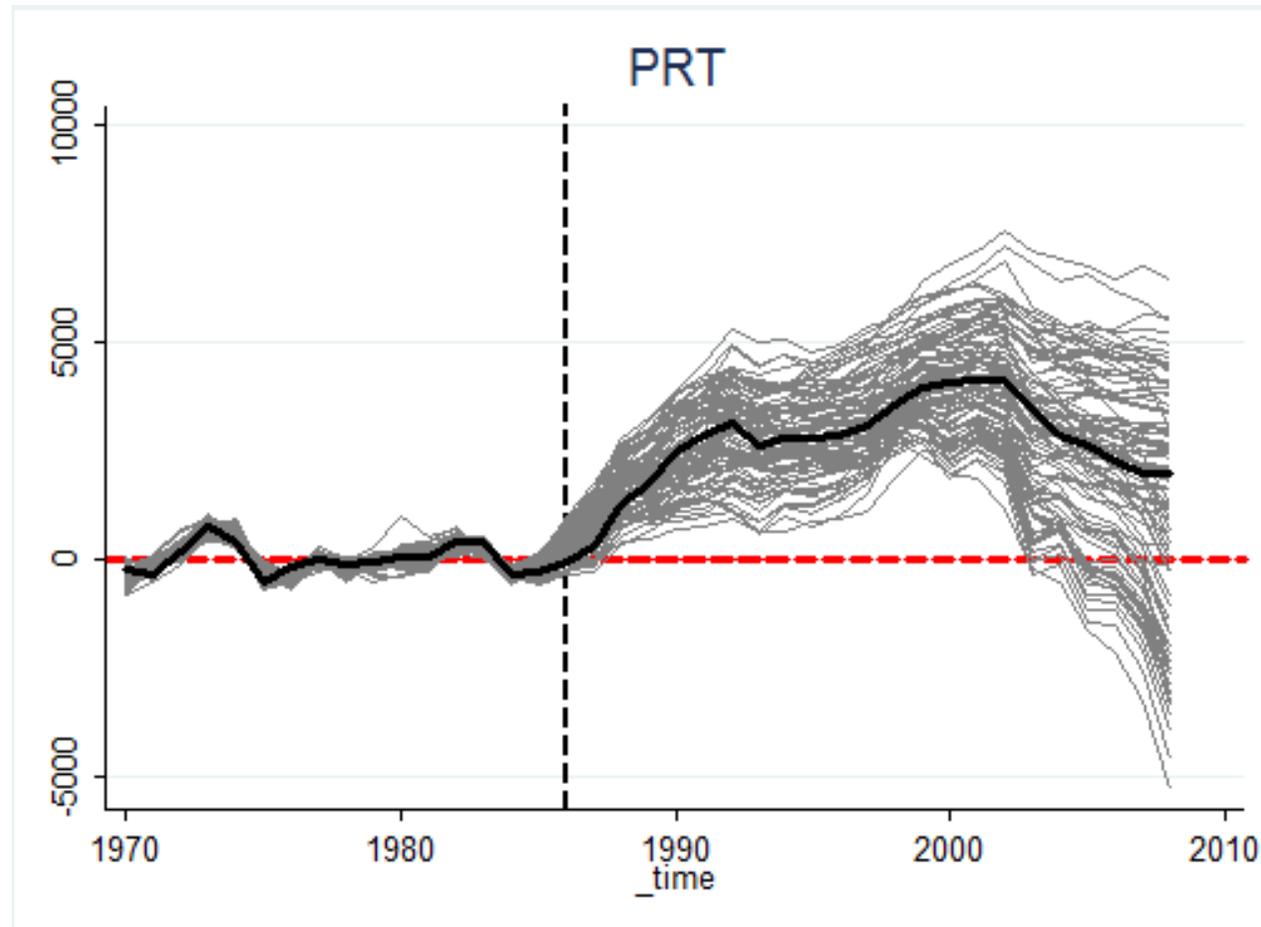

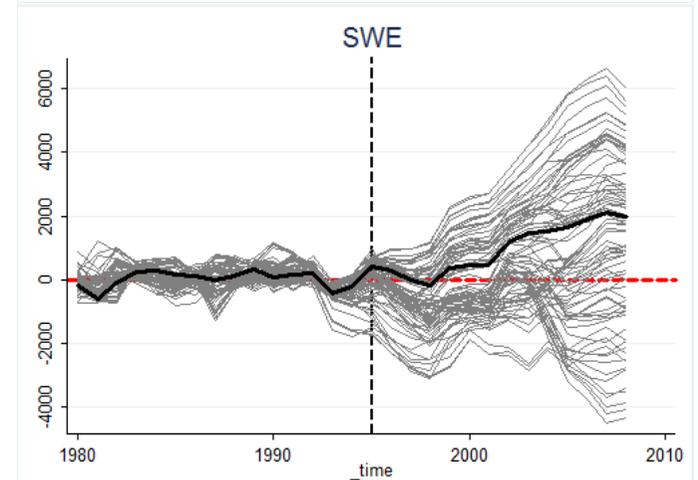

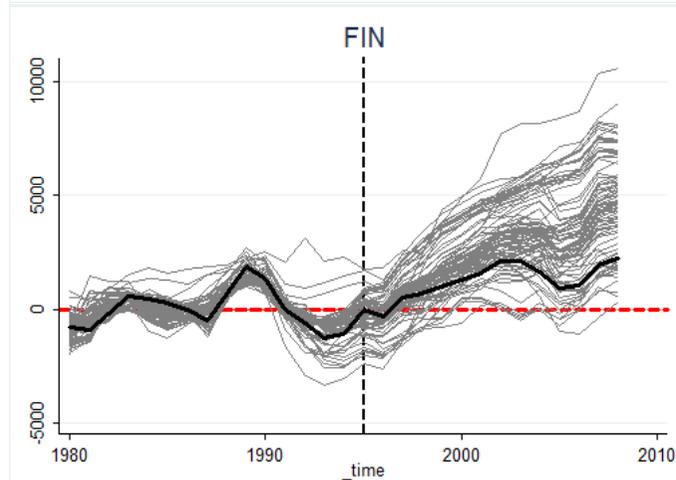

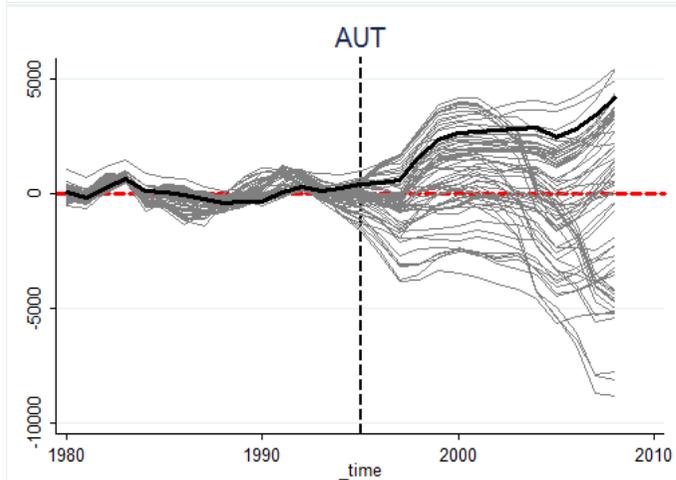

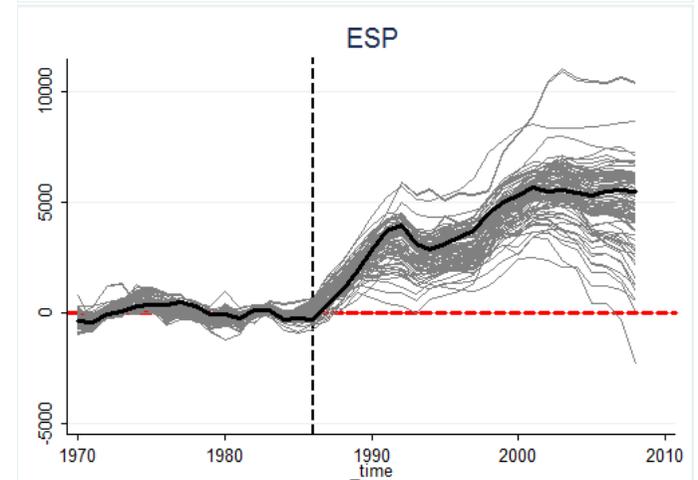

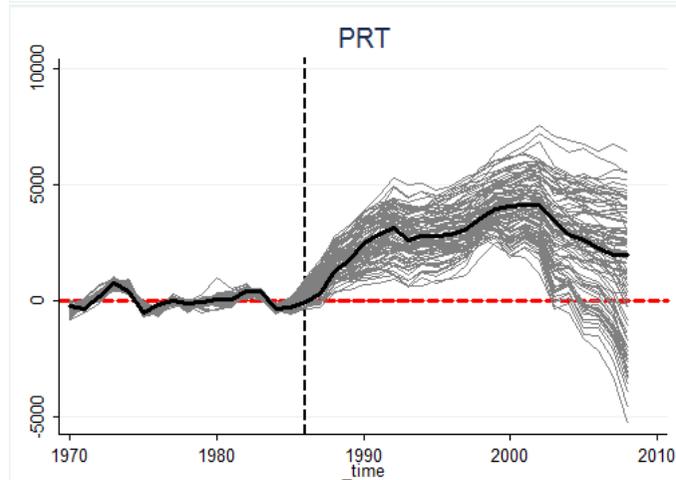

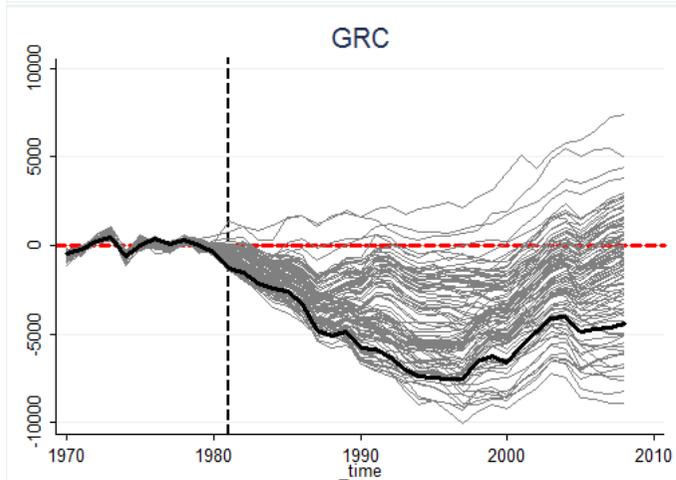

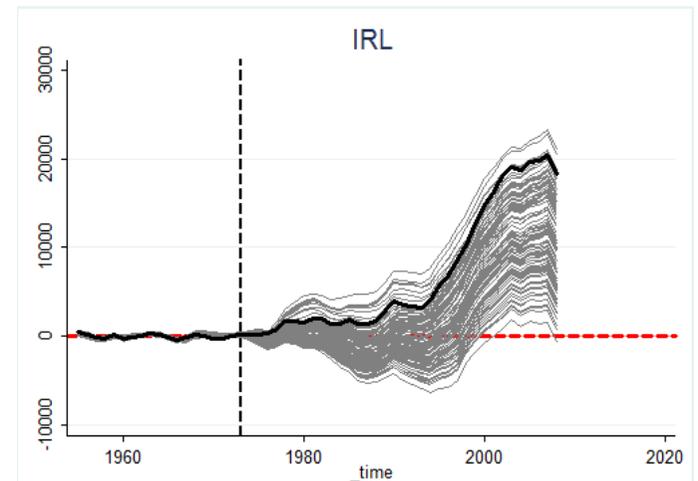

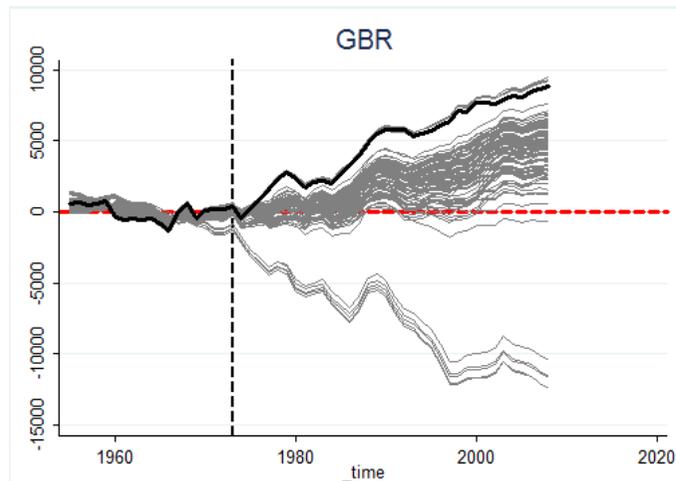

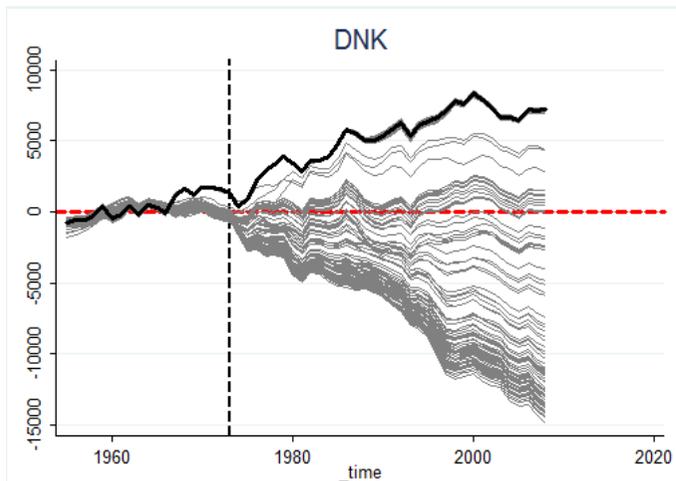

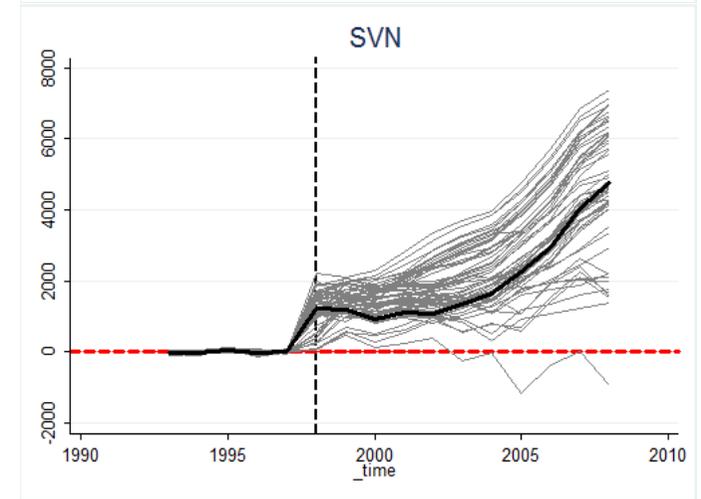

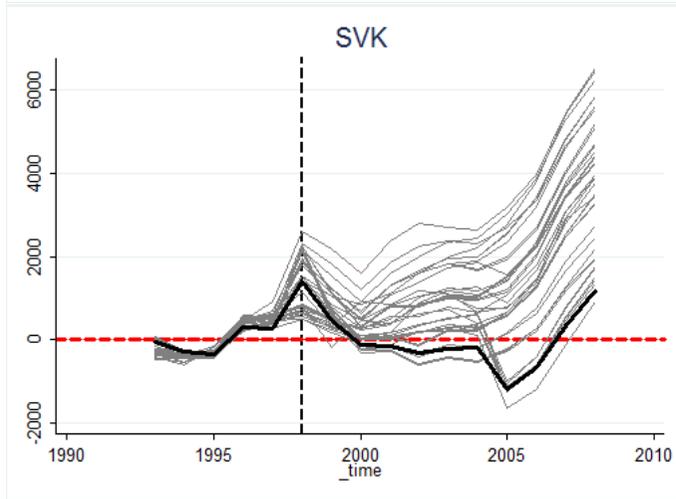

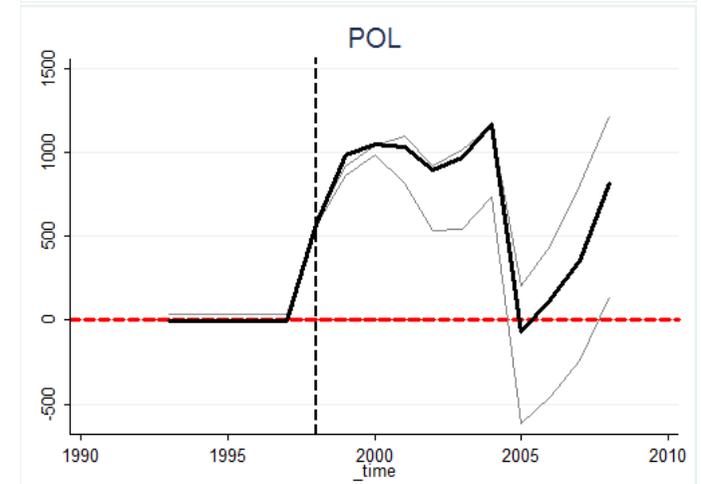

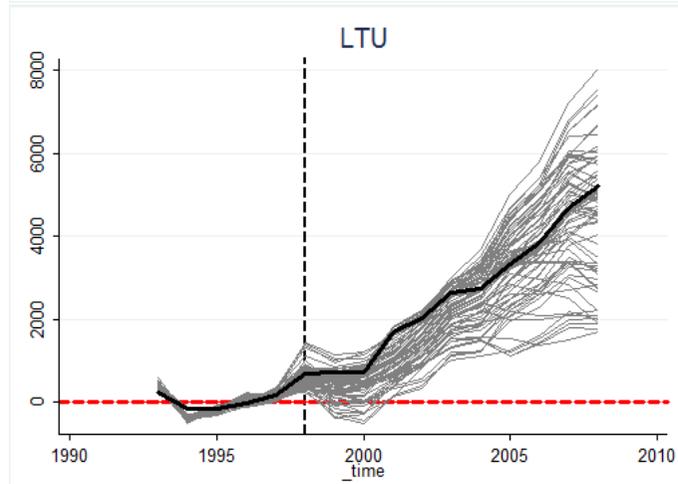

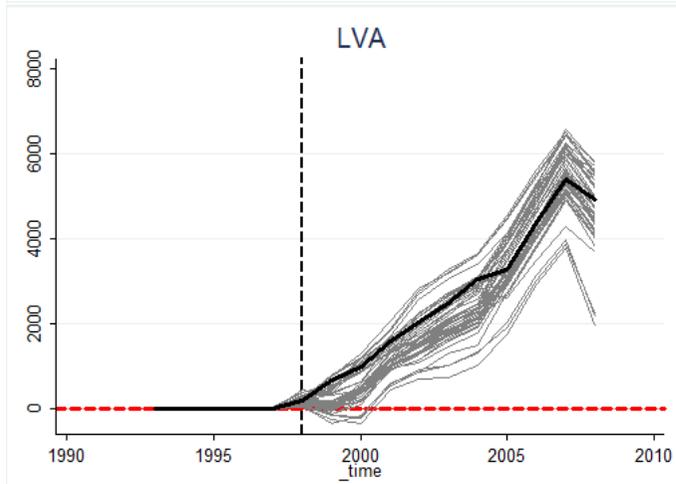

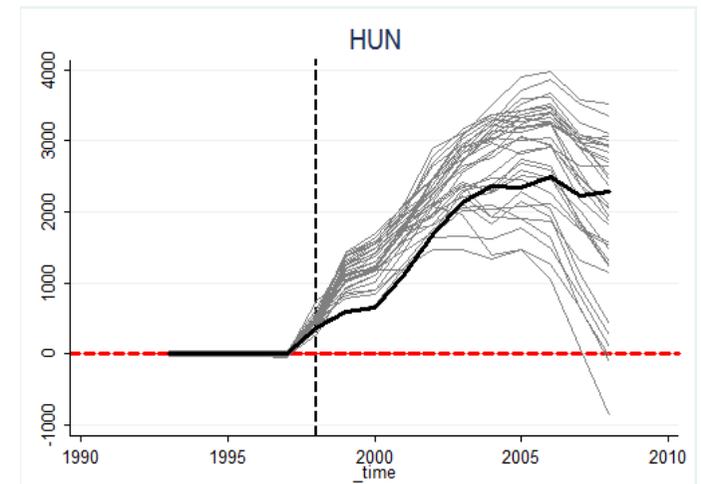

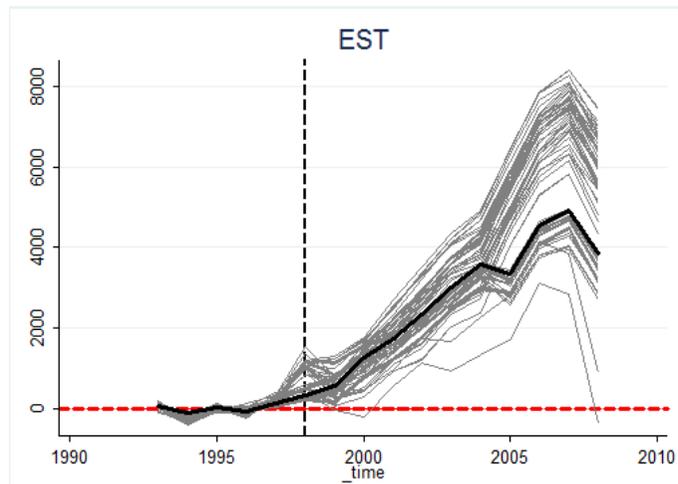

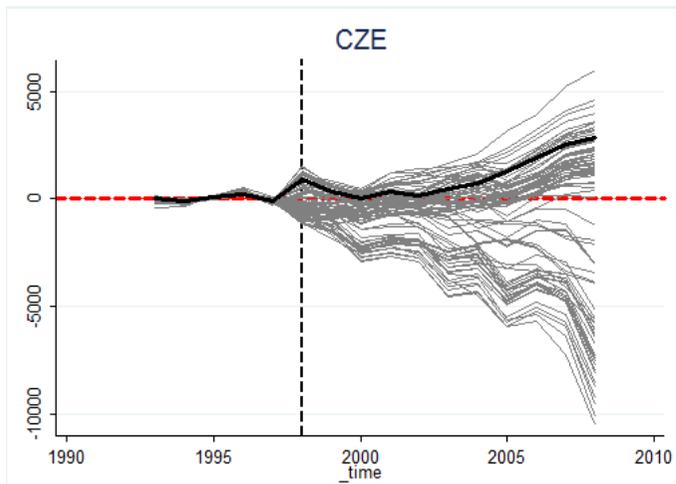

## Testing confidence of the results

- Each donor sample has its own probability of being affected by (minor or large) shocks on the donor countries.
- Thus, each set of weight has its own probability to lead to biased results.
- Eg: Billmeier and Nannicini (2012) run to alternative experiments (whole sample and neighboring countries).
- Eg: Abadie et al (2010, 2014) exclude one country per time from the donor sample and re-run the estimation on the treated unit.
- We suggest a new test and show estimations obtained using **randomly chosen (via bootstrapping) donor samples**:
  - Starting from the whole set of potential comparison countries, we *randomly* construct 1,000 alternative donor samples (each consisting of the same number of countries than our preferred donor sample). If our main estimation is 'in line' respect to most of the 1,000 alternative estimations (with a similar pre-treatment RMSPE), then we can attach a higher level of confidence to our results.

- **SYNTHETIC COUNTERFACTUALS: RANDOM DONOR SAMPLES**
  - Real GDP per capita

## Explaining the gap

It is important to understand the variation across countries and over time in terms of the dividends from EU membership.

We show the association between finance and the dividends from EU membership, after controlling for other factors:

$$GAP_{c,t} = \alpha + \beta GAP_{c,t-1} + \theta Euro_{c,t} + \sigma FinInt_{c,t} + \gamma Trade_{c,t} + \epsilon_{mt}. \quad (1)$$

where:

- GAP is the percentage difference between actual and synthetic GDP series;
- Euro is a dummy variable for countries which joined the common currency;
- FinInt is: (int.liabilities + int.assets)/GDP;
- Trade openness;
- Other controls (e.g. regulation) & country FE & year FE.

VARIABLES	(1)	(2)	(3)	(4)	(5)	(6)

## Campos, Coricelli, Moretti 2015 (CEPR dp)

- *Extension*: Can we disentangle the effects of deep (i.e. political plus economic) integration from those of shallow (i.e. economic only) integration?
- One natural experiment: Norway 1995.
- We find that productivity of Norwegian regions would have been on average 6% higher between 1995 and 2000 if Norway had taken full EU membership.

## Research design

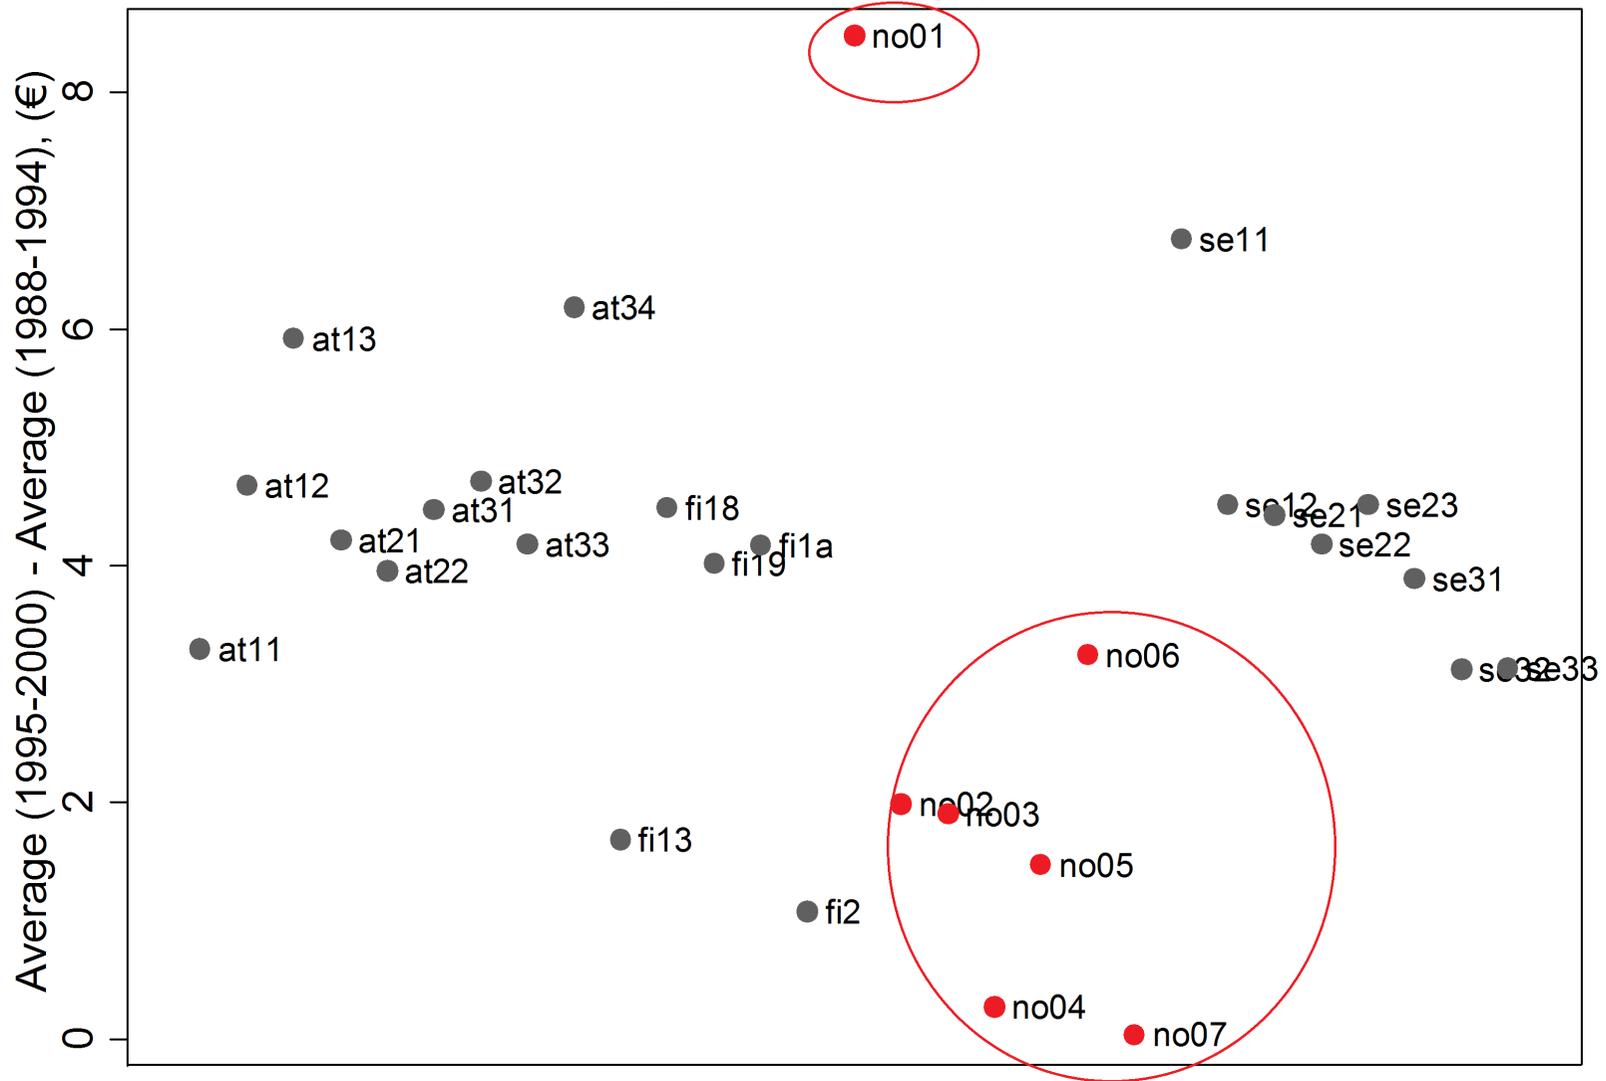

- Our identification strategy uses the 1995 EU Northern Enlargement:
  - In January 1994, four countries (Austria, Finland, Norway, and Sweden) joined the EEA (i.e., enjoyed the benefits from economic integration with the EU through the Single Market).
  - They were all ready to gain full EU-membership from January 1995 (enjoying the benefits from economic plus political integration).
  - In November 1994, in a referendum, 52.2% of Norwegians voted against the EU membership.
  - Since January 1995, AT, FI, and SE are full EU members, while Norway is only EEA member.
- We employ two different estimation approaches:
  - Difference-in-differences.
  - Synthetic control method (SCM).

## Data

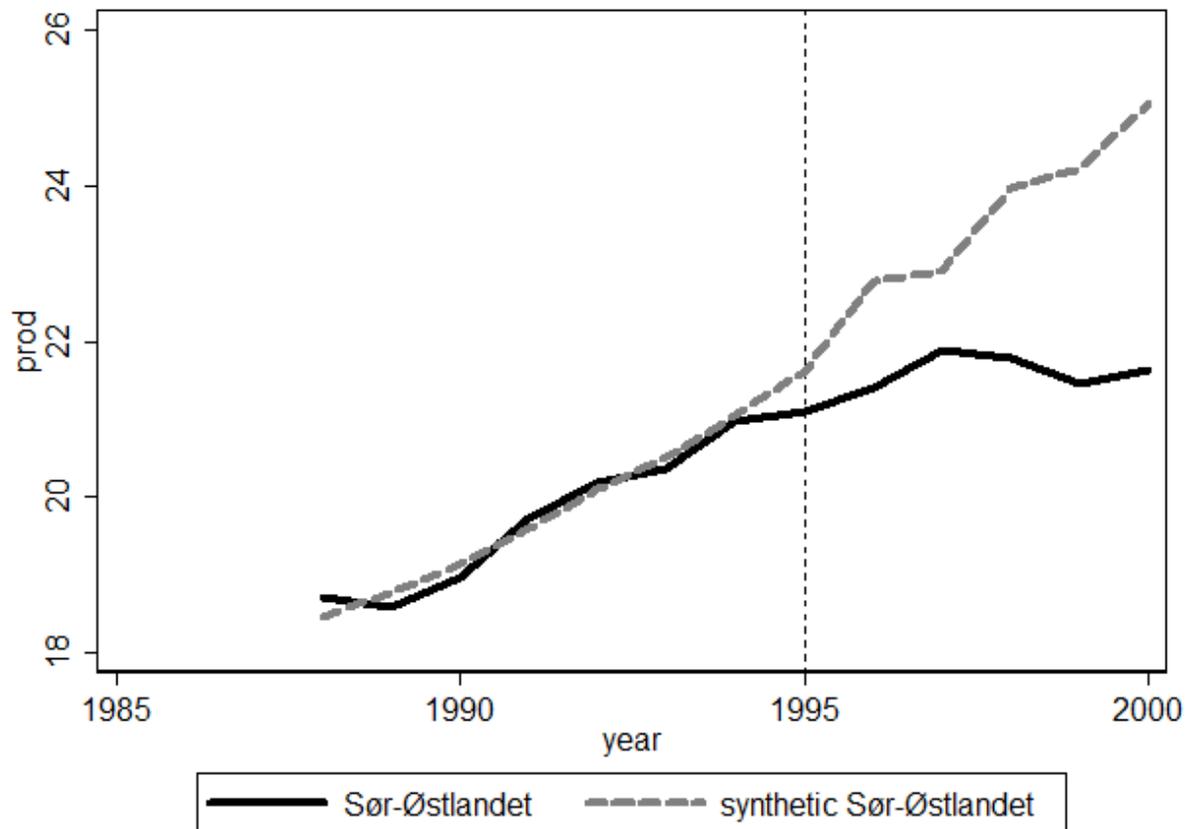

- Period of analysis is 1988-2000: 1988-1994 (pre-treatment); 1995-2000 (post-treatment).
  - After 2000: (i) AT and FI adopted Euro; (ii) EU forced Norway to adopt more common regulation and eliminate its system of special taxation of remote areas; (iii) Norway increased gas exports.
- Data (NUTS2) from Cambridge Econometrics European Regions Dataset (see Becker et al. JPubE 2010, and Tabellini JEEA 2010).
  - We focus on productivity (results are robust to the exclusion of Energy sector).

# BEFORE AND AFTER 1995: Average difference by region

## Difference in productivity per hour worked

# THE SYNTHETIC CONTROL METHOD: Average effects by region

## Placebo experiment on each treated unit

- Abadie et al (2010) suggest to run fake experiments on the control units and assess whether the effect on the treated unit is extreme respect to the effect of the placebo treatment on the controls.

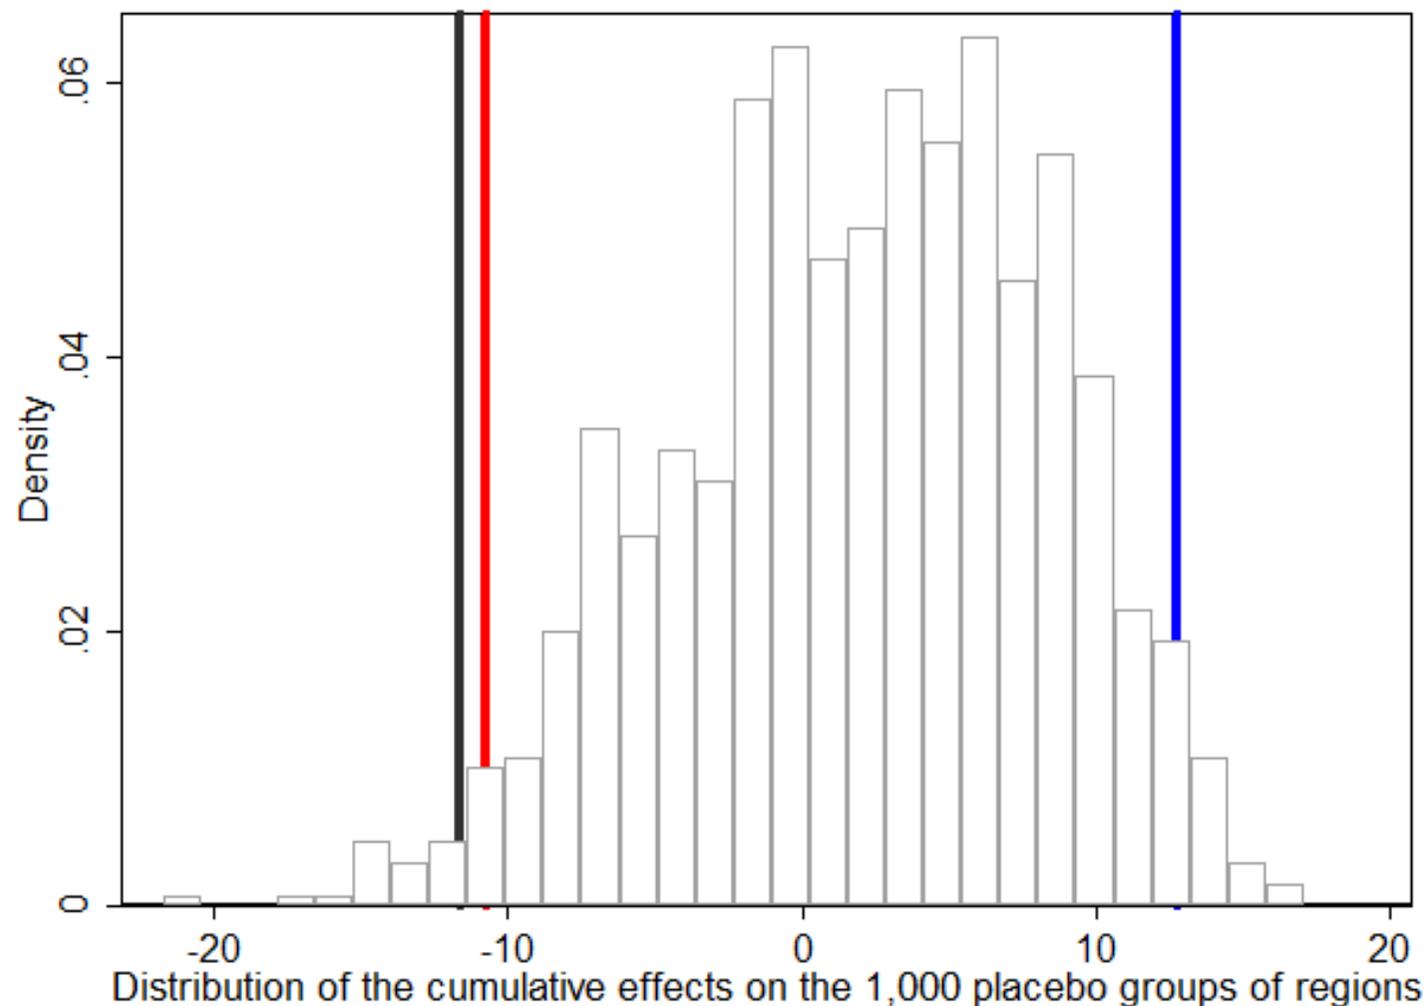

## Placebo experiments on treated group

- We follow Acemouglu et al. (forthcoming, JFinEc) and construct placebo groups (of the same dimension of the treated group), so to compare whether the average treatment effect on the treated group is extreme respect to the effects on the placebo groups.
  - i. We construct 1,000 placebo groups of seven regions randomly chosen from the group of donor regions.
  - ii. We estimate a synthetic counterfactual for each region in each group.
  - iii. We compute an average effect in each group (weighted by the regions' goodness of pre-treatment fit).
  - iv. We compare the average effect on the treated group of Norwegian regions with the effects found for the 1,000 placebo groups.

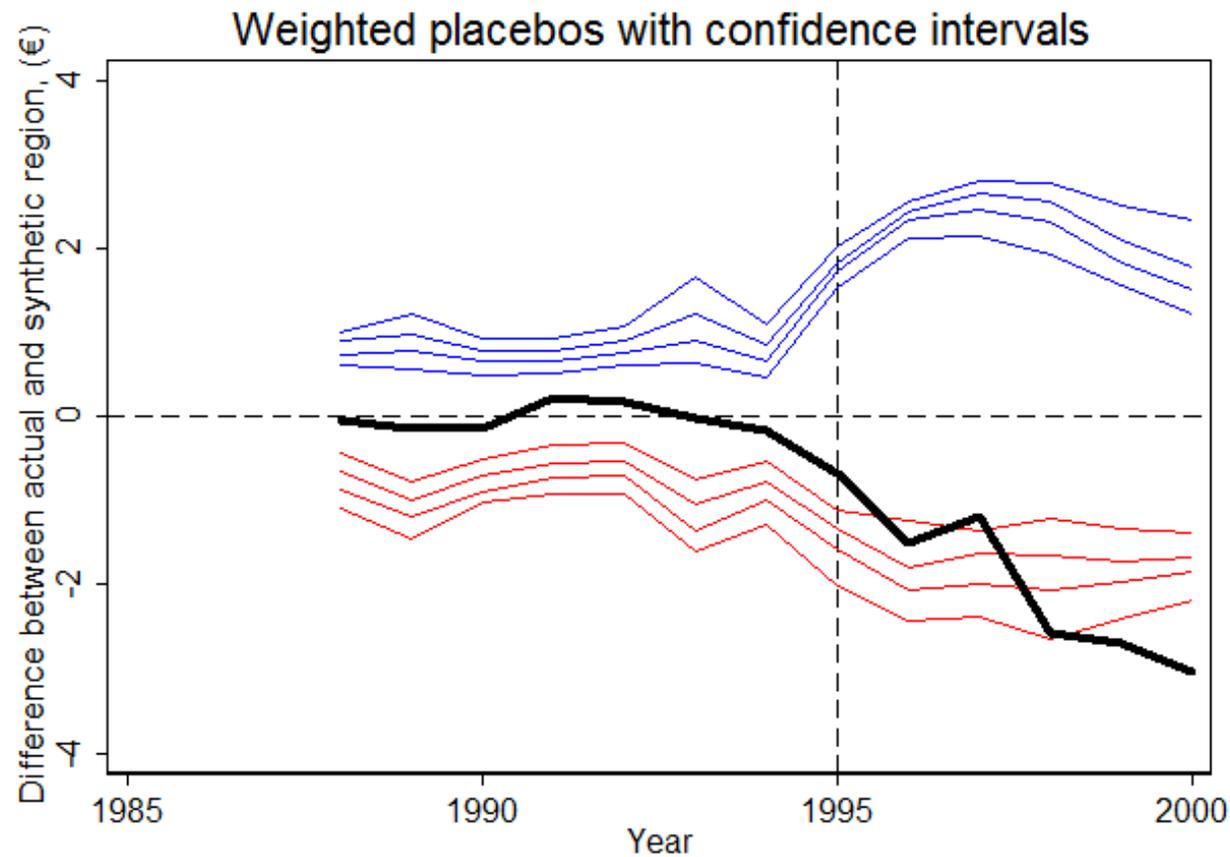

## Placebo experiments on treated group

- The effect on the treated group of Norwegian regions (black vertical line) is at the left of the 2.5<sup>th</sup> percentile of the distribution of placebo effects (red line) → it is negative and extreme respect to placebo effects.

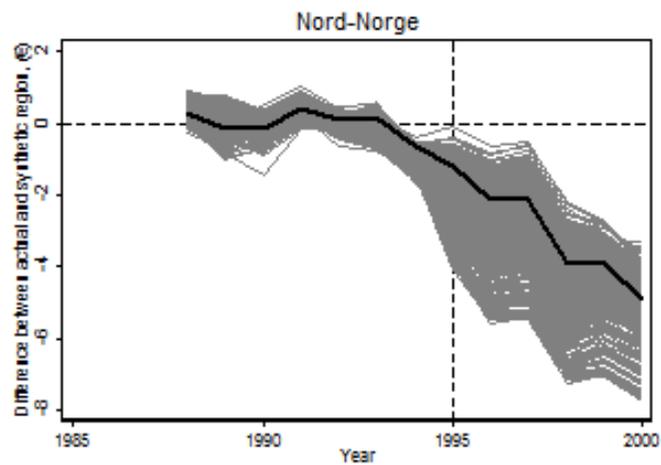

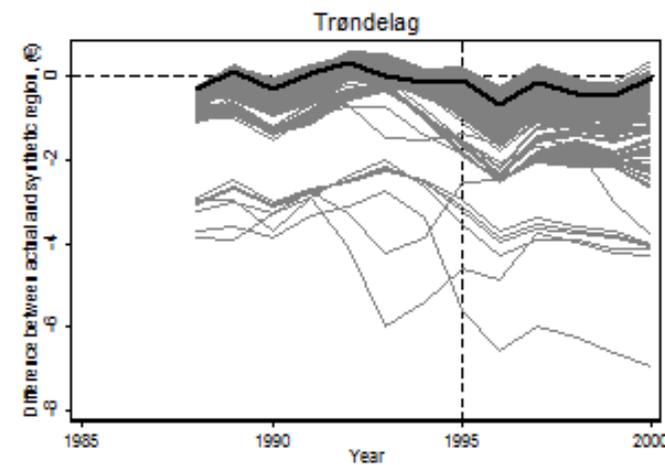

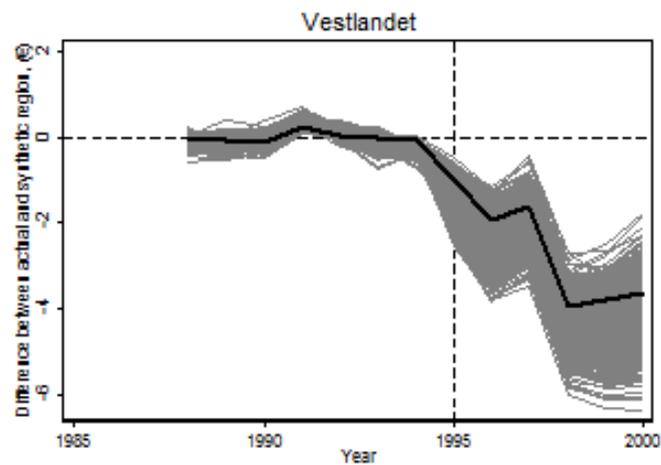

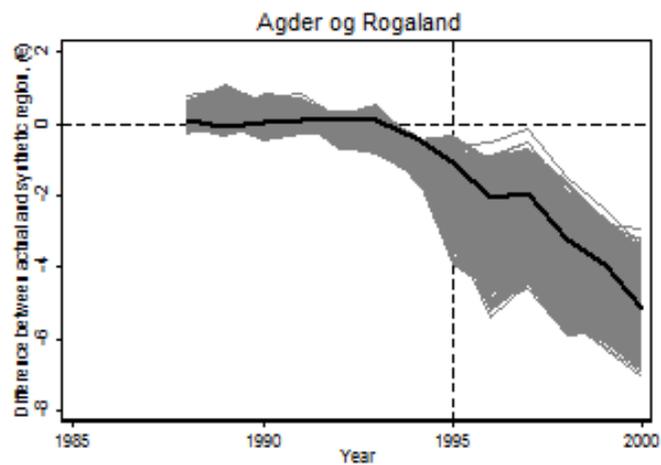

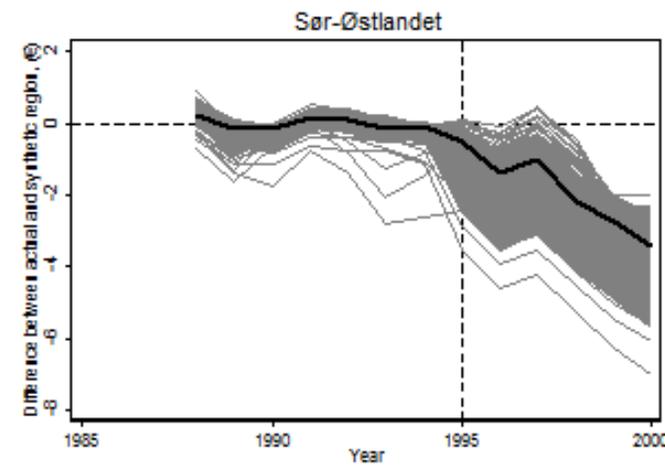

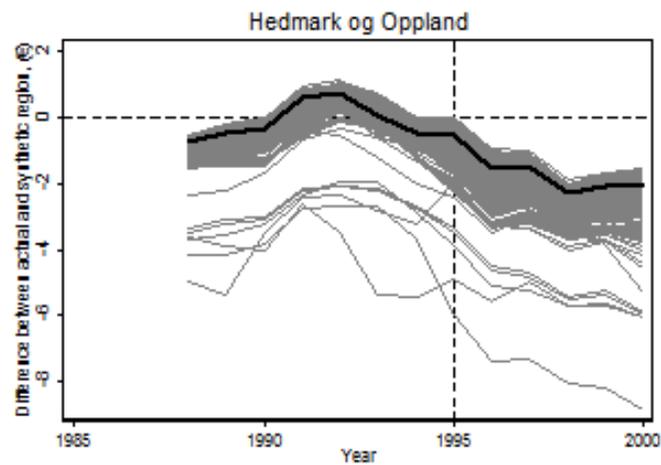

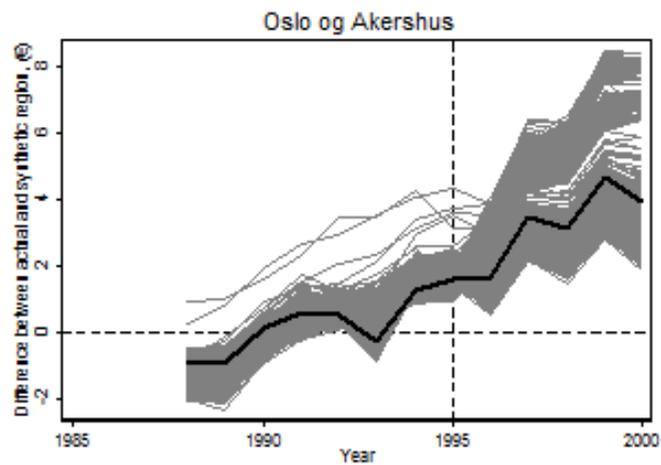

## Placebo experiments on treated group

- We extend Acemoglu et al.'s approach (which is based on the comparison of post-treatment average effects) to obtain comparable placebo effects for each year in the post-treatment.

# Random donor samples

## Interpreting the results

- After 1995, in any Norwegian region (except for Oslo) productivity is lower respect to its counterfactual.
- Explaining heterogenous effects:
  - Peripheral regions represent traditional sectors.
  - Norway's regional policy aimed at protecting and subsidizing those activities.
  - Negative effects on relative productivity.
  - Oslo, with high level of human capital, and efficient public and financial sectors: able to exploit higher benefits of economic integration without political integration.
  - In summary: lacking political integration allowed rent seeking behavior of peripheral regions (Brou and Ruta's argument).
- Voting in EU referendum can help us to interpret the results:
  - Peripheral regions (protected from national policies) voted for staying out of the EU; Oslo voted for joining the EU.

## Conclusion

- SCM allows to run causal inference analysis IN THE FRAMEWORK OF COMPARATIVE CASE STUDIES.
- SCM allows to obtain a unit-specific time-varying estimate of the treatment effects.
- A growing number of papers using this method.
- Appealing for media reports (intuitive method + a single number/effect for each treated unit).
- Need of developing the method to propose systematic ways to assess the statistical significance of the estimates.
